Condition of mineralized tooth tissue in a population of 15-year-old adolescents living in a region of Ukraine with slightly exceeded fluorine concentration in the water. *Ann Agric Environ Med*. doi: 10.26444/aaem/110013

Abstract

Introduction. Fluorine is a common element in nature; however, the difference between a beneficial dose and a toxic dose for the organisms is small. The main source of fluoride for humans is water in addition to food.

Objective. The aim of this study was to estimate the degree of severity of pathological changes, namely, caries or fluorosis, in the mineralized tooth tissue of 15-year-old adolescents with respect to their hygienic and nutritional habits, and the content of fluorine in drinking water, soil and plant products.

Materials and method. 100 adolescents aged 15 from schools in Sosniłka, L'viv region, were examined. The condition of mineralized tooth tissue was evaluated by the caries severity, expressed by the mean number D3MFT, caries frequency and value of the SIC index. Fluorine in plant material and soil were determined according to the PN-G-04543:1982 standard, and water according to the PN-EN ISO 10304 – 1: 2009+ AC: 2012 standard.

Results. Severity of caries disease expressed by the D3MFT number in the examined group of 15-year-olds was 3.39; in the group of girls – 3.08, and in the group of boys – 3.76. In the examined group, the average number of teeth with fluorosis was 7.59. Value of the SIC index among the examined population of students (n=31) was 6.26: 5.89 (n=18) for girls and 7.31 (n=13) for boys. Fluorine concentration in the water was 0.78 – 1.25(mg·dm⁻³). In the soil, it also did not vary across the sampled areas and amounted, on average, to 176 mg·dm⁻³. The biggest fluorine content noted in the dry mass of beetroots was 3.50 (mg F·kg), and the lowest – 3.34 (mg F·kg).

Conclusions. Close to optimal fluorine content lowers caries severity and frequency of fluorosis. Optimal fluorine content in drinking water and food does not require additional diet supplementation

Key words

tooth tissue, fluorine, chemical composition of water

INTRODUCTION

Dental fluorosis is a pathological condition developing during the period of amelogenesis and resulting from the exceeded exposure of teeth tissue to fluorine compounds, i.e. when the total (above optimal) dose of fluorine is present during the critical period for permanent teeth (perinatal to 7 years of age). Clinical image of the enamel changes depends on the severity of the disease. Enamel can be opaque, rough or dull. Single strands may merge in opalescent spots, chalk-white or brown concavities. There may also be a total lack of enamel which leads to a change in the crown of the tooth [1]. The severity of fluorosis depends on the concentration

of fluorine compounds in the drinking water, groceries and tooth-paste, exposure time and individual predispositions [2, 3, 4]. According to Skorkowska-Zieleniewska et al. [5], fluorine accessibility from water is 60% and from food 35%. Fluorosis mostly affects the permanent teeth: premolars, second molars, upper incisors and fangs, where the mineralization period occurs later in life [6], most probably due to the greater accessibility of fluorine compounds to older children. As a result of ongoing industrialisation, hence, polluting the environment with fluorine compounds, the WHO recommends that optimal dose of fluorine in drinking water as 0.5 – 1 ppm [7].

Fluorine pollution affects all elements of the ecosystem. Fluorine compounds in the soil are found mainly in the humus layer and the fluorine content depends on organic substances and the bedrock [8]. Since water, soil and atmosphere are the main sources of fluorine for plants, its content in the

above-mentioned environments indirectly influences its accessibility for humans [9]. Plants uptake fluorine through diffusion and the cell wall constitutes the main barrier to its accumulation [10]. Excessive concentration of this element in plants changes enzymes activity, adversely affects the process of photosynthesis, inhibits growth and increases biomass [11].

OBJECTIVE

The aim of this study was to estimate the degree of severity of pathological changes, namely, caries or fluorosis, in the mineralized tooth tissue of 15-year-old adolescents with respect to their hygienic and nutritional habits, the content of fluorine in drinking water, soil and plant products.

MATERIALS AND METHOD

A group of 15-year-old adolescents (index age group approved by the WHO) attending schools in Sosnilka, Lviv region of Ukraine, was clinically tested. In total, there were 100 participants of both genders. The tests were conducted in standardized conditions with disposable dental kits, and attention paid to sterility and non-invasiveness for the patients. All examinations were carried out in dental surgeries, secured and prepared by the testing team with disposable materials. The tests were performed in the light of a lamp for dental use, a mirror and a WHO probe. Data were collected in anonymous and coded case report files. Clinical evaluation of the patients' oral health was carried out in compliance with WHO guidelines and suggested criteria (Oral Health Surveys: Basic Method, 5th Edition, 2013). All the doctors conducting the tests had received training connected with the calibration process, from which a mean standard error was estimated. Cohen's kappa compatibility factor of the test results was 0.97. The results were verified by secondary random sampling of 10% of patients. The condition of mineralized tooth tissue was evaluated by the caries severity, expressed by the mean number D3MFT, caries frequency and value of the SIC index.

Evaluation of the condition of mineralized tooth tissue in view of fluorosis was performed in compliance with the WHO guidelines and Dean's criteria [12]:

- D0** – correct dentition /enamel surface is smooth and shiny of creamy-white colour.
- D1** – questionable fluorosis / enamel surface with clearly marked deviations from correct transparency (a few white spots).
- D2** –very mild fluorosis / small, whitish, opaque, irregular patches on less than ¼ of the tooth surface.
- D3** – mild fluorosis / white opaqueness of the enamel is more widespread, but does not exceed 50% of the tooth enamel.
- D4** – moderate fluorosis / enamel surface is considerably damaged with frequent brown stains.
- D5** – severe fluorosis / the whole surface is damaged; hypoplasia is so extensive that tooth shape can be altered; either small or extensive pitting or brown discolorations; tooth often corroded.

Socio-medical tests constituted the second part of the research. Questions, adjusted to the age of the patients

were included in the questionnaires, coded with the same numbers as the patients case report files. The questions concerned nutritional and hygienic habits and included the following parameters: frequency of fresh fruit and vegetable consumption, frequency of teeth brushing, use of fluoride toothpaste. The obtained results were statistically analyzed. Values for measurable parameters were presented as values of average, median, minimum and maximum values, lower and upper quartile and standard deviation, and for the immeasurable ones, as multiplicity and percentage.

Test Chi² was used for quality features to detect the dependence between analysed variables, whereas the Mann-Whitney U test was used in order to examine differences between two groups. Level of significance of $p < 0.05$ indicated statistically significant differences or dependencies. The database and statistical studies were performed on Statistica 9.1 software (StatSoft, Poland).

Plant material, water and soil were sampled from the area of Sosnilka village, and randomly divided into three parts. Three farms were chosen from each part for analysis of vegetables (beetroot), water and soil. Fluorine content in the sampled material was determined. Plant material and soil were determined according to the PN-G-04543:1982 standard, and water according to PN-EN ISO 10304 – 1: 2009+ AC: 2012 standard by the ion chromatography method (IC).

RESULTS

Because 10 questionnaires were inadequately completed, only 90 of the 100 15-year-old participants, indigenous inhabitants of Sosnilka, were qualified for test analysis. Among the middle and high school students, 54.44% (n=49) were girls and 45.56% (n=41) boys.

Caries frequency was estimated at 86.67% and was lower in the group of girls (81.63%) than in the group of boys (92.68%)

Severity of caries disease expressed by the D3MFT number in the examined group of 15-year-olds was 3.39; in the group of girls – 3.08, and in the group of boys – 3.76. In the examined group, the mean value of D3T was 2.44; 2.39 for girls and 2.51 for boys. Mean value of the MT number was 0.035 and pertained to boys only. Mean value of number the FT was higher for boys (1.17) and lower for girls (0.69). The differences were not statistically significant. Table 1 presents mean values of the D3MFT number and its components D₃T, MT, MF in the group of 15-year-olds.

Table 2 presents mean values of number D3MFT and its components for patients diagnosed with fluorosis and for patients without fluorosis. Mean value of D3MFT in the group with fluorosis – 2.59 and in the group of people without fluorosis – 3.73. The differences were not statistically significant. Statistically significant differences were observed only for the FT component – 0.48 and 1.10, respectively ($p = 0.020$).

Table 3 shows the statistically significant correlation between the number of teeth with fluorosis and the D3T value ($p = 0.015$); FT ($p = 0.047$); D3MFT ($p < 0,001$); namely, more teeth with fluorosis corresponded with lower values of D3T, FT, D3MFT (negative correlation).

No statistically significant correlation between the MT value and the number of teeth with fluorosis ($p = 0.614$) was noted.

The value of SIC index among the examined population of students (n=31) was 6.26, with 5.89 (n=18) for girls and 7.31 (n=13) for boys (Tab. 4).

Table 5 covers the number of people diagnosed with fluorosis. In the tested group it was present in 30% of patients (n=27); in 28.57% of girls (n=14) and in 31.71% of boys (n=13). No statistically significant difference in correlation with gender and fluorosis incidence was noted (p=0.746).

Table 4. Mean values of SIC index in the examined group of 15-year-old adolescents with respect to gender

Specification	M	Me	Min.	Max.	Q1	Q3	SD	Difference at p level

	70.00%	30.00%	

In the examined group, the average number of teeth with fluorosis was 7.59; 9.93 for girls and 5.08 for boys. Comparing the tests results, it was concluded that there were more teeth with fluorosis in the population of girls (median: 7; interquartile range: 4–16) than in the population of boys (median: 4; interquartile range: 2–6), which was statistically significant (p=0.038) (Tab. 6).

Table 6. Number of teeth with dental fluorosis in examined group of 15-year-old adolescents with respect to gender

Specification	N	M	Me	Min.	Max.	Q1	Q3	SD	Difference at p level

N – number; M – mean; Me – median; Min. – minimum value; Max. – maximum value; Q1 – bottom quartile; Q3 – upper quartile; SD – standard deviation; p – statistical significance.

In the examined group, there were 27 cases (6.67%), (n=6) of questionable fluorosis (D1), and 21 cases (23.33%) of very mild to severe fluorosis (D2-D5). In order to determine which teeth were most frequently affected by fluorosis, the dentition was divided into 6 sextants: sextant I: average number of teeth affected by fluorosis – 0.67, sextant II: 3.52, sextant III: 0.96, sextant IV: 0.48, sextant V: 1.30 and in sextant VI: 0.67. The majority of teeth affected by fluorosis was observed in sextant II (Q1-Q3: 1–6) (Tab. 7).

Table 7. Number of teeth with dental fluorosis in examined group of 15-year-old adolescents regarding teeth sextants

Sextants	N	M	Me	Min.	Max.	Q1	Q3	SD
Sextant I (18–14)	27	0.67	0	0	4	0	1	1.18
Sextant II (13–23)	27	3.52	4	0	6	1	6	2.52

Sextant VI (44–48)	27	0.67	0	0	4	0	1	1.24

M – mean; Me – median; Min. – minimum value; Max. – maximum value; Q1 – bottom quartile; Q3 – upper quartile; SD – standard deviation.

Socio-medical analysis shows that all examined patients brushed their teeth with fluoride toothpaste and water. In the group of people with diagnosed fluorosis, 34.38% (n=11) brushed their teeth once a day, 29.02% (n=16) at least twice a day. Three patients who brushed their teeth less than once a day were not included in the analysis. The number of daily hygienic treatments did not affect the incidence of fluorosis (p=0.607) (Tab. 8). Table 9 presents the correlation between incidence of fluorosis and the use of fluoride toothpaste. Questionnaire responses show that 61 participants (67.77%) brushed their teeth with fluoride toothpaste; among them, 31.15% (n=19) were diagnosed with fluorosis. 28.57% (n=8) of the participants who did not use fluoride toothpaste were

	75.00%	25.00%	
Total	63	27	
	70.00%	30.00%	

also affected by fluorosis. However, the differences were not statistically significant (p=0.998).

Table 10 shows the relation between prevalence of fluorosis and consumption of fresh fruit and vegetables. Fluorosis was diagnosed in 31.82% (n=21) of patients eating fresh fruit and vegetables every day, and in 25.00% (n=6) of those eating vegetables every 2–3 days or once a week. There was no statistically significant correlation between the frequency of eating fresh fruit and vegetables and prevalence of fluorosis (p=0.716).

The data concerning frequency of fresh vegetables and fruit consumption by the patients diagnosed with fluorosis is presented in Table 11. Taking into consideration only the patients with fluorosis, a statistically significant difference was observed in the number of teeth with fluorosis between those who ate fruit and vegetables every day and more often (U=27.0, p=0.036), and those who ate them every 2–3 days or only once a week.

Table 11. Mean number of teeth with dental fluorosis and frequency of fresh vegetables and fruits consumption in examined group of 15-year-old adolescents

Specification	M	Me	Min.	Max.	Q1	Q3	SD	Difference at p level

M – mean; Me – median; Min. – minimum value; Max. – maximum value; Q1 – bottom quartile, Q3 – upper quartile; SD – standard deviation; p – statistical significance.

Table 12 presents the results of chemical analysis of fluoride content in water, soil, and plant material. The analysis concludes that fluoride concentration levels were not significantly different between the three studied materials in the sampling area. Fluorine concentration in the water was 0.78 – 1.25 (mg·dm⁻³). In the soil, it also did not vary across the sampled areas and amounted, on average, to 176 mg·dm⁻³. The biggest fluorine content noted in the dry mass of beetroots was 3.50 (mg F·kg), and the lowest – 3.34 (mg F·kg).

Table 12. Fluorine content in soil, water and vegetables in Sosnilka

Research area	Water (mg·dm ⁻³)	Soil (mg·dm ⁻³)	Plant material (mg·kg)
I	0,78	174	3,40
II	1,25	177	3,50
III	1,08	177	3,34
Me	1,10	177	3,40
Mean	1,04	176	3,41

DISCUSSION

The research revealed that caries frequency in the group of 15-year-old adolescents living in the area of Sosnilka was high – 86.67%. Studies conducted in Malawi by Msyamboz et al. [13] showed that caries frequency was 21.9%, evidently much lower. Similarly, Chinese and Mexican authors observed a considerably lower caries frequency – 24.4% [14] and 48.6% [15], respectively. Higher values of caries frequency were noted in United Arab Emirates – 65% [16] and Iran – 75.5% [17]. However, the highest caries frequency was recorded in youths from cities in north-west Russia – 91.8% [18] and in Lithuania – 92.9% [19].

Caries severity was estimated with the value of mean D3MFT number. In the available literature, published values of mean D3MFT number varied and fluctuated from 0.45 in China [14] and 5.44 in Lebanon [20] to 5.6 in Lithuania [19]. Own data is lower than the results obtained from examining 15-year-old youths in L'viv, Ukraine, in 2012 – 5.18 [21] and 2015 – 5.58 [22]. Values of the D3MFT number similar to those obtained in Sosnilka – 3.39, were also recorded in Greece – 3.19 [23], Georgia – 3.51 [24], and India – 3.82 [25].

The results of epidemiological data of mineralized tooth tissue, based on analysis of the D3MFT number, should be considered in correlation with the values of its particular components – D3T, MT and FT.

Studies conducted in L'viv in 2012 revealed the following values of particular components of D3MFT: D3T – 2.52, MT – 0.05, FT – 2.61 [21], and in 2015: D3T – 3.35, MT – 0.06, FT – 2.86 [22]. The studies by Smolar showed that the D3MFT number in Sosnilka was 2.00 [21]. D3T values obtained in different countries varied considerably. The D3T value in a group of 15-year-old adolescents from Russia was 2.61 [18], while in Macedonia it was only 0.56 [26]. The ratio of D3T to MT and FT may indirectly expose the quality of dental care and pro-health habits of the population.

In own research, in order to identify patients with a high severity of caries, the SIC index (Significant Caries Index) was applied. Statistical analysis showed that the index value was 6.26. Considerably higher values (10.8) were recorded in 2011 for a population of Polish children [27]. Research conducted in 2015 L'viv, Ukraine, concluded that the SIC value for 15-year-old adolescents was 10.13, and for peer adolescents from Lublin, eastern Poland – 7.3 [22]. Hilt recorded SIC value of 8.20 [28], while for 15-year-old youths from Macedonia – 8.93 [26], and for Greek youths – 7.07 [23]. A much lower SIC value of 3.46 was obtained from studies by Pontiago-Loyola et al. [15].

Dentists working in Sosnilka area in 1994 and 2012 reported a fluorine level in drinking water of 4.00 ppm and 1.64 ppm, respectively (Fig. 1–5). After changes in water supply and modernisation of the water supply network, in 2016 the fluorine level was estimated at 1.01 ppm, on average, although in some research areas it was 1.25 ppm. The examined group of 15-year-old adolescents was exposed to high fluoride levels through odontogenesis. Fluorine concentration over 1 ppm in drinking water increases aluminum adsorption, causing degenerative changes and collagen breakdown [30]. A fluorine content over 1.5 ppm causes mottling of teeth, while its concentration above 3.0 ppm leads to skeletal fluorosis [10]. In studies conducted in Poland by Jędra et al. [31], the fluorine content in drinking water was estimated as low: 0.09 mg·dm³ in (Sosnowiec) –

Figure 1–5. Clinical cases of fluorosis according to Dean Classification (D3-D5) in examined group

0.32 mg·dm³ (Olsztyn). The current study showed fluorosis in 30.00% of the examined 15-year-olds. Identical results (30%) were obtained by Carvalho et al. [32]. In Germany, fluorosis was diagnosed in 7.1% – 11.3% of patients [33], in Nigeria – 12.09% [30], in Brazil – 17.2% [34], in India – 24.5% [35], in Yemen – 30.8% [36], and in Mexico – 59% [37]. By comparison, Ramesh M. et al. [38] reported very high dental fluorosis frequency (63.1%) in a group of people living in the endemic fluorosed districts of Salem and Tamil Nadu. Naidu et al., when examining 15-year-old youths from Prakasam District in South India diagnosed dental fluorosis in 82.04% of the populations [39].

The highest average number of teeth affected by fluorosis in the examined group from Sosnilka was recorded in sextant II – 3.52 and sextant V – 1.30. Bhavagatula et al. [3] proved that dental fluorosis was most frequently observed in upper incisors and least frequently in lower incisors. Studies by Sudhir [40] in Nalgonda, Andhra Pradesh District, south-east India, did not reveal any statistically significant differences between mandibular and maxillary incisor teeth. However, different results were obtained while examining 15-year-olds from Costa Rica. Salas-Pereira et al. [41] diagnosed the most severe form of dental fluorosis (moderate to severe) mostly in sextant III (25%) and sextant II (12%). According to de Moura et al. [42], the premolars were the teeth most affected by fluorosis. Wiener et al. [43] revealed that in a similar age group, 31.2% of those examined did not have dental fluorosis, 7.5% were diagnosed with questionable fluorosis and 61.3% with very mild and above. Own studies conducted in Sosnilka present respective values of 70.00%, 6.67% and 23.33%. Different data concerning fluorosis severity in youths in Mexico is reported by de Lourdes Azpeitia-Valdez et al. [44]: very slight – 45.5%, slight – 40.0%, moderate – 11.8%, and severe – 2.6%. Nelly Molina-Frechero et al. [37], while examining Mexican youths reported the following values: 29.3% – very mild fluorosis, 20.9% – mild fluorosis, 6.7% – moderate fluorosis, and 2.1% – severe fluorosis. Studies conducted by Celeste and others [45] on a large group of adolescents showed a prevalence of questionable cases (18.8%), very mild, mild or moderate cases of dental fluorosis (11.5%), and no severe cases observed. From a group of 1,026 students, 64.3% were detected with dental fluorosis, more than 50% had either severe or moderate fluorosis according to the Dean's fluorosis Index [46].

Research by Al-Akwa et al. [47] revealed a negative correlation between caries frequency and fluorine concentration in drinking water (0.61–2.00 ppm F).

The conducted research revealed a highly significant negative correlation between the number of teeth affected by fluorosis and caries severity ($p < 0.001$). A considerable influence of fluorine level in drinking water on the prevalence of dental fluorosis was detected by the research of Firempong et al. [48] in Ghana. In an examined group of youths from Bongo town, 63.0% were diagnosed with dental fluorosis, whereas among those from villages outside the town – less than 10.0%.

Analysis of own questionnaire showed that 61% of the examined youths brushed their teeth twice a day. Similar results were obtained by Carvalho et al. [32]. In both cases, no statistically significant correlation was observed with fluorosis incidence ($p = 0.607$). Lack of correlation between frequency of teeth-brushing and the type of toothpaste ($p > 0.15$) was pointed out in the study by Celeste et al. [45].

Molina-Frechero et al. [37] revealed a correlation between fluorosis and more frequent teeth-brushing. Children who brushed more often had 28.5% more cases of fluorosis than those who brushed less frequently.

The available literature does not contain any studies concerning the correlation between prevalence of fluorosis and intake of fluorides from diet supplementation preparations and plant products. Similar conclusions were drawn by Bhagavatula et al. [3], whereas Khandare and Rao [9] claim that water and food are the main sources of fluoride for the humans. Fluorine content in plants depends mostly on its concentration in the soil, chemical composition of the soil, especially the amount of calcium and phosphorus, as well as the type of soil [10, 49].

In own studies in Sosnilka, the average concentration of fluorine in the soil was 176 mg·dm³. Kulczycki et al. [50] determined 3.53 to 4.52 mg F·kg⁻¹ in the soil around a chemical plant near Bolesławiec in Silesia, south-west Poland. Kłódka et al. [51] stated that dissolved fluorine concentration in the soil influences its content in root vegetables. For leafy vegetables, the main sources of fluorine are its gaseous compounds. The authors determined 10–45 mg F·kg⁻¹ in beetroot dry mass. In own studies, these values were much lower – 3.40 mg F·kg⁻¹, on average. A higher concentration of fluorine in beetroot was reported by Kusa et al. [52] – 15.91–29.04 mg F·kg⁻¹. It can be assumed that despite the quite high content of this element in water, its uptake by plants was impeded. Long-lasting, permanent fluoride contamination, even minimally exceeding the standards, is a toxic factor, thus its presence in the environment should be constantly monitored [53].

CONCLUSION

Close to optimal fluorine content lowers caries severity and frequency of fluorosis. Optimal fluorine content in drinking water and food does not require additional diet supplementation.
